

IMPROVING WATER SECURITY IN PERI-URBAN AREAS AROUND BANGALORE

Arvind Lakshmisha and Priyanka Agarwal

Senior Program Officers, Public Affairs Centre, Bangalore, India
Email: arvindsha@pacindia.org

Abstract: *Growing urban population have increased the pressure on ecosystems specifically water resources. While the urban demographics is changing, climate change is affecting the hydrological cycle affecting the precarious balance between availability and demand. Agenda 2030, calls for inclusive and participatory approach to reduce poverty and achieve the set goals. The paper delineates how a participatory and inclusive approach can lead to reducing water insecurities in the global south. It explains the use of fuzzy cognitive maps to capture stakeholder knowledge to help bridge the gap between scientific research and policy making through stakeholder participation.*

Key words: Participatory water management, Climate Change, Peri-urban areas.

Introduction

India's carbon contribution is lower than many other developed/developing countries of the world. But this is set to change dramatically in the coming decade due to increasing urban population. As urban population grows, pressure on ecosystems increases, large quantities of food, fuel and water need to be moved into urban areas and huge amounts of garbage and sewage have to be moved out (Impact of Climate Change on Urban Areas in India. 2010). Water resource, one of the most vital and the most abused resource, is the best example of the precarious relationship between urban areas and natural systems. Over the past decade, a new amalgamated space that straddles the boundaries of urban areas has been drawing the attention of scholars. Known as the 'Peri-Urban Interface' (PUI), this area is defined as 'zone of (dynamic) transition or interaction between urban and rural areas; usually used in the context of rapidly urbanizing poor countries' (Simon, 2008). These dynamic zones are the main sources of supply of resources such as water to meet the needs of urban areas and act as recipients of waste generated within the surrounding urban areas. Hence, we can ascertain that there is a bi-directional flow between urban and peri-urban areas resulting in a flux or a dynamic state which is in transition.

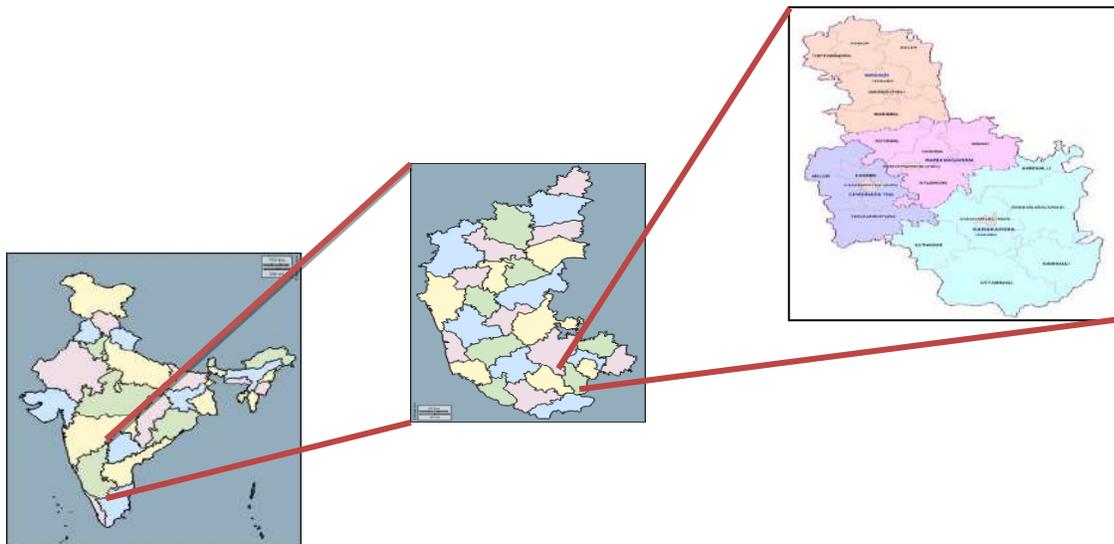

While urban demographic transformation is unfolding, the changing climate is expected to affect the hydrological cycle. This change is likely to affect precipitation patterns, with some areas becoming wetter and other becoming drier. In this regard, the trends in climate and demographics will pose a fundamental challenge, how will water be provided to urban areas in a sustainable manner (McDonald, et al., 2011). To evaluate how climate change will affect the precarious balance between water availability and demand, it is crucial to assess the entire array of social costs or benefits of any change in water availability and use. Institutions that

govern water resources, play an important role in determining the overall water security in view of the impacts (*social*), as well as sectoral gains and losses (IPCC, 2007). United Nations, define water security as “the capacity of a population to safeguard sustainable access to adequate quantities of acceptable quality of water for sustaining livelihoods, human well-being, and socio-economic development to ensure protection against water-borne pollution and water related disasters, and to preserve ecosystems in a climate of peace and political stability” (United Nations, 2013). Access to potable water and sanitation is considered a basic human right and yet billions do not have easy access to these services. It is estimated that approximately 1.8 billion people use a water source that has faecal contamination and approximately 40% of the world’s population suffers from water scarcity (United Nations, 2016). The UN’s Sustainable Development Goal 6 and Goal 11 address this shortcoming by aiming to provide clean water and sanitation to all by 2030, through an inclusive and participatory process. While water crisis is a common phenomenon across developing countries, India has the largest population of 76 million people who do not have access to clean water. A much larger proportion of the country’s population is faced with water scarcity and is forced to make do with irregular access to water (Water Aid India, 2016).

Study Area

The study area is located in the periphery of Bangalore city, known as the silicon valley of India. Eight villages located 60kms from the city falling under the jurisdiction of Manchanayakanahalli gram panchayat were chosen. According to the Census of India 2011, the region though, under the jurisprudence of the gram panchayat (rural) has nearly 96% of the working population classified as main workers and a majority of them are seen to be engaged in activities other than agriculture, which can be described an urban characteristic¹.

Figure 1: Study Area

¹The Indian census defines urban areas as any area with more than 70% of the population engaged in non-agricultural activities.

Methodology

The study approach is based on the principles of constructive engagement and emphasises the need to move research away from top-down, extractive information gathering to participatory, bottom-up and inclusive knowledge generation. Hence, Climate Change Score Cards (CCSC), developed by PAC was used to develop community centred scenarios based on stakeholder inputs in this study. This study focuses on citizen-centred scenario planning as a practical and potentially powerful tool for local-scale vulnerability analysis and adaptation planning in social–ecological systems within the context of multiple interactions and stressors. Community-based scenario water resource planning is proved to have significant potential as an anticipatory action research process for incorporating multiple stressors into vulnerability analysis and adaptation planning (Bennet, Kadfak, & Dearden, 2016).

Climate Change Scorecard

Climate change scorecard (CCSC) is an adaptation of the community score card (CSC), consolidates peoples' opinion and facilitates an informed dialogue between communities and the local governance structures. In the case of climate change there are not two, but three important dimensions: the people, the state and the environment. To account for this, systematic integration of information on local governance, local climate and livelihoods was established using CCSC. The tool supports communities to prioritize issues and provides a platform for dialogue with relevant decision makers. Climate change scorecard is undertaken in four distinct phases: an initial exploratory phase; analytical phase; synthesis phase and policy discourse with stakeholders (local government, community, industry representatives).

Interviews and Drawing Fuzzy Cognitive Maps

The stakeholders were chosen based on the demographics and employment type of the study villages. Each group drew three maps identifying the impact of increase in temperature, variation in rainfall and urbanisation on water security in their respective villages. Maps were developed with the aid of local communities to assess their perceptions of how urbanization coupled with changing climate has impacted water security in peri-urban areas. In this research 30 interviews were conducted with stakeholders belonging to four different stakeholder groups. In total 221 people (86 men and 135 women) participated in the drawing of 240 maps. Before the exercise of drawing cognitive maps with the stakeholders, the field staff drew their own maps to understand the local ecosystem. This was to make the interviewers realise their biases while drawing maps with the stakeholders.

Table 1: Classification of stakeholder for drawing cognitive maps

Categories	No. of Groups		Total Number of Maps in each category (per village)	Total No. of Participants in each category (in all villages)	
	Men	Women		Men	Women
Agricultural Labourers	1	1	6	21	25
Livestock Herders	1	2	9	21	46
Industrial Labourers	1	1	6	21	22
Farmers	1	2	9	23	42
Total per village	4	6	30	-	-
Total no. of participants in each group (in all villages)				86	135

Cognitive maps were drawn as prescribed by Ozesmi U, (1999) and Carley & Palmquist, (1992). The interviewer listed the names, occupation and gender of the correspondents on the chart paper. The stakeholders were explained the reasons behind the research before the start of the interview. Once the correspondents understood this, they were asked: *'If I mention variation in Rainfall and water security, what are the factors, things, variables that come to your mind?'* Similarly, questions were asked for increase in temperature and urbanisation. The interviewees were then asked to list the factors on the paper. Once listed the respondents were asked to explain the relationships between the variables and draw lines between them to represent their relationships. Respondents are then asked to mark these lines with arrows to indicate their directions, and give signs of positive or negative and strengths: high (1), moderate (0.5) and low (0). The process continued till the interviewees felt they had nothing more to add, thus completing the map. After the completion of the maps, they were transformed into adjacency matrix according to principles of graph theory. The variable V_i was listed on vertical axis and V_j on the horizontal axis thus, forming a square matrix.

Condensed Cognitive maps and calculating the indices

The square matrix developed by individual stakeholders was combined into village wise cognitive maps by adding the augmented matrices as developed by Kosko, (1988). Each of the stakeholder maps were given equal weightages before being condensed. Condensation is undertaken to reduce the complexities associated with fuzzy cognitive maps, due to numerous variables and connections between them. As FCMs are quite complex, graph theory indices provide as simplified way to analyse their structure (Ozesmi & Ozesmi, 2003).

The first step is to identify the number of variables (N) and the number of connections (C) in the condensed map. The density of the cognitive map (D) is an index of connectivity: $D = C/(N(N-1))$ or $D = C/N^2$ if the map has self-loops i.e., if a variable can have a causal effect on itself (Ozesmi & Ozesmi, 2003). The variables are defined as out degree ($od(V_i)$), row of sum of absolute values of a variable in the adjacency matrix and shows the cumulative strength of connections (a_{ij}) exiting the variable. The in degree [$id(V_i)$], is the column sum of absolute values of the variables and shows the cumulative strength of connection (a_{ij}) entering the variable. This calculation is used to identify the transmitter variables [indicating forcing functions] which have a positive out degree and a zero in degree. The receiver variables [indicating utility functions] have a zero out degree and a positive in degree. Ordinary variables have positive out degree and in degree (Bougon, Weick & Binkhorst, 1977; Eden, Ackerman, & Cropper, 1992; Harary, Norman, & Cartwright, 1965). Furthermore, the centrality of a variable is assessed to calculate the contribution of a variable in a cognitive map, which is the summation of the in degree and out degree (Harary, Norman, & Cartwright, 1965).

Results

The results of the analysis of the information gathered and generated in the four phases of the study reveals that water insecurity in these areas is more likely to be a function of high demand and poor management; rather than absolute scarcity of water. The study findings indicate that the region is home to numerous water bodies which are either encroached upon and/or polluted and cannot be used for consumption. The Arkavathy River flows through the study area, but is

highly contaminated as it is the main channel for flow of sewage from the city of Bangalore and also the industrial estates located upstream. This section details the results from the climate data analysis, interviews and questionnaire surveys conducted and the capture of stakeholder [local] knowledge to prioritise options to reduce water insecurities.

Climate Data Analysis

Climate data for the district was analysed based on the data provided by the Indian Meteorological Organisation. There is no local [village] level data available for the time period (1901-2000) and hence, the paper had to make do with the district level data. The time series analysis, of the average temperature of the region for the years 1901-2001 indicates that there is an increase in temperature of nearly 0.5° centigrade in the last century. An analysis of the annual rainfall between the years 1901-2010 indicates a large variation in the region and it can be seen that has been erratic with increase in the intensity of rainfall but decrease in the number of rainy days.

Figure 2: Average Annual Temperature (1901-2002)

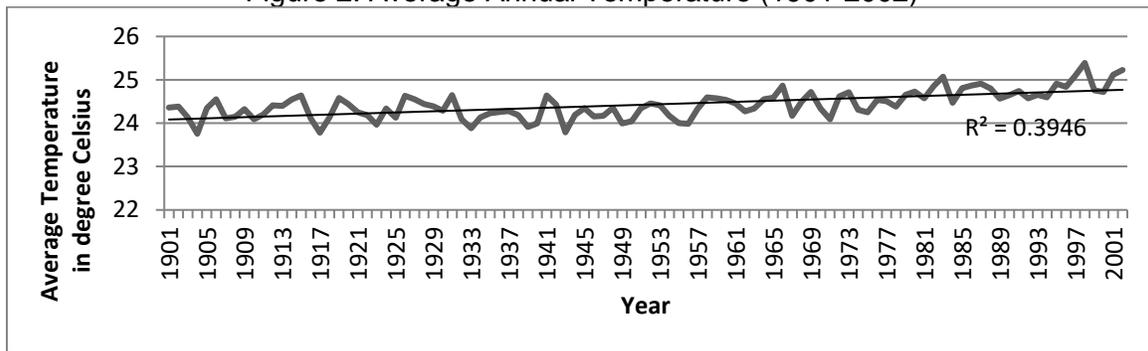

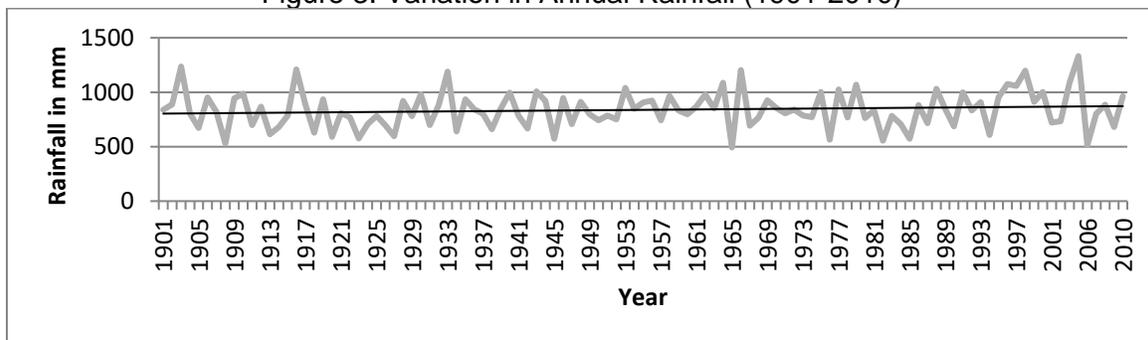

Figure 3: Variation in Annual Rainfall (1901-2010)

Stakeholder perception on water security

The findings of the survey and interviews with GP members and industrial representatives are classified through the lens of accessibility, quantity and quality of water and are detailed in this section.

Survey Findings

Water Accessibility and Quantity

The survey findings revealed that 95 % of the households in the region possess an easy access to water either in the form of tap at home or public taps located within 500 meters from their homes. Majority of the households possess a tap at home (73 per cent) which is the main source of drinking water. Apart from this, public taps formed the next major source of drinking water as reported by nearly 24 per cent of the respondents. On the contrary, 58 per cent of the respondents purchase mineral water for drinking purposes from water vendors, which raises questions on the quality of water used by the communities for drinking, and other household usage.

Water Quality

The supply of salty and muddy water was also reported in a few villages. These factors led to assessment of water quality in the villages where the quality of water was described by the households as not up to the standards, in addition to depending on other sources such as water vendors. The samples included water from drinking water sources², groundwater and water supplied through public tap by the Gram Panchayat. The water samples from the purifications plants were seen to contain higher pH values highlighting that the water supplied is acidic in nature. Two samples including a sample from the purification plant was found to be slightly muddy or earthy in addition to presence of metal in one of the water sample collected from a household. Apart from the above findings, it was also revealed that there is a lack of awareness among the households regarding measures that can be adopted by households to improve both surface and groundwater sources. Only 44 per cent of the households mentioned to have gathered some information about rainwater harvesting from television and other sources of media.

Interviews with GP members and Industries

Water Accessibility and Quantity

Household water is supplied by the local government through various schemes and programs and they indicated that they are able to meet only 80% of the demand. The remaining 20% is usually through private tube wells and the purification plants set-up in conjunction with the industries. There is also a mention of the increase in the number of private tube wells (individual and collective) who have also given rise to an informal business of water supply through tankers within the area to supply water to water starved Bangalore city. In regard to drinking water 90% of the households purchase water from the purification (Reverse Osmosis) plants set-up by the local governments in collaboration with industries located in the region under their CSR activities. The industry representatives mentioned that they are mostly dependent on groundwater to meet their demands. Large industries located in the area also identified themselves to be recycling water and are working hard to create water positive or water neutral footprints.

² Reverse Osmosis plant and hand pump serve as a major source of drinking water in some villages.

Water Quality

Similar issues identified during the water sample analysis were also reflected in the interviews with the Gram Panchayat members and industrial representatives. The overarching issue of unsustainable rate of groundwater extraction connects all stakeholders interviewed. The local government representatives highlighted that there has been a drastic decrease in the levels of groundwater in the past decade from 400 to nearly 850 feet. Considering that all stakeholders in the area draw water from a common aquifer, the decisions of individual stakeholders impact the entire community in the area. Given the current lack of formal regulations against excessive water extraction, policy intervention may be necessary to ensure sustainable water management. With regard to water quality all the stakeholders are aware that water resources in the region are highly contaminated and are not suited for consumption but are still highly dependent on groundwater to meet all their requirements. The state government has declared groundwater in the region to be fluoride contaminated and has declared the groundwater to be unsafe for drinking. Though purification plants are set-up and being used, an analysis of the water sample conducted by the study team indicated low P^H content with metal corrode in some of the collected samples.

Modelling Policy options using Cognitive Maps

The 240 fuzzy cognitive maps drawn were condensed into a single condensed map, it is evident from Figure 5 that the strongest connections are between variations in rainfall and affecting agriculture practices, availability of drinking water, quantity of drinking water including surface and groundwater available. In Figure 5, the size of the block indicates the influence the variable has on other variables; the black lines indicate a positive impact and the red lines depict a negative impact of one variable on the other. Rainfall, temperature and urbanisation including agriculture and financial conditions seem to be the most influential variables in all the maps drawn. It can be seen that the variables of Agriculture, Groundwater, surface water and drinking water are highly negatively impacted as there are a high number of red links directed towards them (Lakshmisha, Agarwal, & Nikam, 2017).

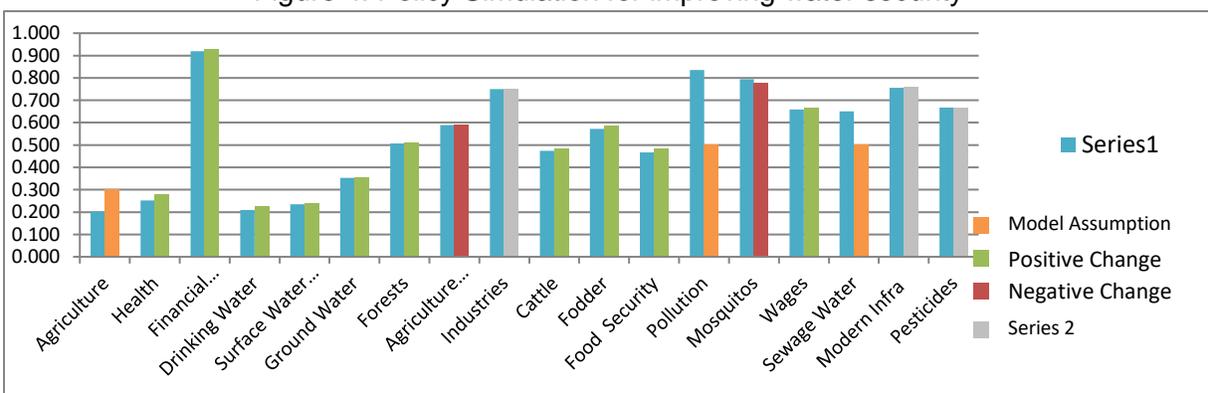

Variation in rainfall is also said to reduce the food security of the communities; Increase in Temperature is seen to affect agricultural practices, reduce health of the communities, availability of fodder and hence cattle in the region and financial conditions in addition to water sources (ground and surface) and drinking water. Temperature is also seen to affect forests in a negative way. Whereas Industries are seen to have the highest impact on financial conditions of the local communities, this increase in financial conditions are seen to be offset by spending on health related issues caused due to changing climate and increasing urbanisation; Urbanisation is said to increase the sale of agricultural land, leading to increase in the number of industries and the level of pollution due to improper waste management systems. The maps also suggest that there has been an increase in the modern infrastructure facilities in the study area as a result of urbanisation (Figure 5).

Therefore from the map we can say that, if we are to improve the water security in the area which is negatively impacted by climate change and aggravated by urbanisation (Lakshmisha, Agarwal, & Nikam, 2017). There is a need to reduce pollution and reduce the conversion and sale of agriculture land. The map also indicates a positive relation between

surface water bodies and groundwater; hence there is a need to improve surface water bodies such as lakes and tanks, present in large numbers in the region to improve groundwater, thus reducing the level of contamination and providing quality drinking water. This improvement in water sources will result in improved agriculture practices, as the current practice uses contaminated effluent water to cultivate crops which in turn harm the health conditions. Thus, improving water security will also lead to alternative benefits such as improving the health conditions of the communities, through improved food security (Lakshmisha, Agarwal, & Nikam, 2017).

Modelling different policy options in a fuzzy cognitive map helps identify and selecting the alternatives to achieve the goal of improving water security in the region. This paper presents just one example out of the six policy models simulated for the study. The policy simulations were performed on the condensed cognitive map that includes an aggregation of individual maps drawn by all stakeholders with equal weightages. Steady-state conditions were first determined and all the variables were set to the value of 1. Various policy options were run on the models, a variable was fixed at 1 if a variable was to be kept high or fixed at 0 if it was to be eliminated. In this paper we highlight one of the six cases of policy options that were run. The case run included various ways to increase water availability. The proposed changes included reduction of pollution and sewage water (fixed at 0) and improving agriculture practices as shown in Figure 4. Modelling these assumptions we can see that, there is a positive change in the health, and drinking water availability in the region. Whereas, a moderate positive change can be seen in water (surface and ground) sources, in addition to forests and thus, fodder available resulting in a surge in the cattle population and thus improvements in the dairy sector. These outcomes also result in a strong positive increase in the financial conditions of the community (Lakshmisha, Aggarwal, & Jangal, 2016). Thus, improving agriculture practices and reducing the current levels of pollution through effective enforcement of current policies is found to improve water security in the region. This improvement in the water sector will have positive repercussions on the health and financial conditions thus reducing local vulnerability to the impacts of climate change.

Figure 4: Policy Simulation for improving water security

Policy Discourse and Dialogue Platform

In line with the principles of constructive engagement, the findings from the study were shared with all the stakeholders at a dialogue platform. The platform was a culmination of community members, local government representatives, experts, bureaucrats, and industry representatives (Lakshmisha, Aggarwal, & Jangal, 2016). The study findings were shared and policy options were simulated with inputs from these stakeholders present. The highlights of the dialogue platform are as below:

- The community members and industrial representatives called for the establishment of a common effluent treatment plant in the region to help recycle industrial effluents
- There was a call for decentralised sewage treatment plants and for up-gradation of the current plant from a secondary trickling mechanism to a tertiary treatment plant
- The local government invited industry representatives for an increased and improved communication/interactions
- The local government in conjunction with industry representatives decided to undertake awareness programs on building capacity of the community on water conservation measures
- The industry representatives have called to work together with local government to establish rainwater harvest structures to help improve the quality and quantity of groundwater
- The senior bureaucrat from the department of ecology, forests and environment, Government of Karnataka directed the rural department to undertake rejuvenation of surface water bodies under the famed National Rural Employment Guarantee Scheme

Conclusion

Agenda 2030 focuses on robust implementation to enhance inclusively and sustainable urbanization and capacity for participatory, integrated and sustainable human settlement planning and management (SDG 11). The unplanned nature of development has resulted in indirect consequences in peri-urban areas which has wider implications on water security of the area. This paper assessed the double injustice brought upon due to unchecked resource extraction and changing the climate on peri-urban communities. Simultaneously, a framework has been delineated for the need of inclusive and participatory planning to achieve the SDGs, specifically the goal 11. The framework highlights how citizen-centered scenario planning is a practical and potentially powerful tool that can be used as an anticipatory action research process (Lakshmisha, Agarwal, & Nikam, 2017).

Involvement of all stakeholders in the planning process is called for in most of the targets under SDGs. A stakeholder-centric design to identify issues based on perspectives of the local communities will help in incorporating multiple stressors into planning. This paper captures local knowledge of the communities and highlights how urbanization has changed the lifestyle of this agrarian Gram Panchayat which is further aggravated due to changes in climate. The issues identified acts as the foundation upon which solutions can be devised. The approach of this paper depicts how social concerns of citizens and communities can be mobilized to forge a collective will (Lakshmisha, Agarwal, & Nikam, 2017). Thus, the paper concludes that *“If we need a sustainable world for 2030 and beyond, we need to ensure responsive, inclusive, participatory and representative decision-making at all levels (SDG 16)”*.
